Hypertension remains a major contributor to the global burden of disease. The measurement of blood pressure continues to have pitfalls related to both physiological aspects and acute variation. As the left ventricle (LV) remains one of the main target organs of hypertension, and echocardiographic measures of structure and function carry prognostic information in this setting, the development of a consensus position on the use of echocardiography in this setting is important. Recent developments in the assessment of LV hypertrophy and LV systolic and diastolic function have prompted the preparation of this document. The focus of this work is on the cardiovascular responses to hypertension rather than the diagnosis of secondary hypertension. Sections address the pathophysiology of the cardiac and vascular responses to hypertension, measurement of LV mass, geometry, and function, as well as effects of treatment.

PATHOPHYSIOLOGY OF CARDIAC RESPONSES TO HYPERTENSION

Left Ventricular Hypertrophy

Size and Geometry of the Normal Heart. The main contribution of echocardiography to the management of hypertension is the assessment of left ventricular (LV) mass (LVM). Body habitus represents one of several factors that confound the association between hypertension and LVM. However, cardiac size is influenced by body size, and for any given size, men have larger hearts than women, athletes have larger hearts than non-athletes, and obese subjects have larger hearts than non-obese subjects.1 LVM and volumes bear an approximately quadratic (rather than approximately cubic) relationship with height in men and women.2,4

In the enlarged heart, wall (fibre) stress increases with LV size (radius and volume). This increase is compensated by a proportional increase of wall thickness, so that wall stress remains matched with the systolic pressure. The ‘relative’ geometry of the ventricle appears to be similar across species and body size, with normal relative wall thickness (RWT, the ratio of twice the posterior wall thickness (PW) and the LV diastolic diameter) from 0.32 to 0.42.5 Mass/volume ratios corresponding to the above-mentioned normal RWTs range between 1.1 and 1.3.6 RWT and M/V do not require correction for body size.

Effect of Gender. Data from several studies indicate that after adjustment for blood pressure and anthropometric parameters, LV volume and LVM are higher in men than in women.5,6 These differences persist when values of LVM are corrected for fat-free mass.3 This sex difference may explain the surprising lack of consensus in appropriate indexation of LVM, as it impacts the optimal method for indexing LVM for body height. Figure 1 displays LVM, calculated by the Devereux formula (unidimensional 2D measurements) in the healthy reference subgroup of the Asklepios population.1 Using the allometric index 1.7, the body height–LVM relationship in men (red) and women (blue) is parallel and indexation for body height is optimally achieved by height (ht)1.7 in both sexes.10,11 However, when an allometric exponent is computed for males and females considered together (thick black line) without adjustment for gender, there is an exaggeration of nonlinearity in the height–LVM relationship when the confounding effect of sex is neglected.11 This particularly leads to estimation problems at the extremes.

Effect of Exercise and Sport. Isotonic exercise involves movement of large muscle groups. The profound vasodilatation of the
skeletal muscle vasculature that is involved produces hypertrophy by increasing venous return to the heart and volume overload. This hypertrophy is characterized by chamber enlargement and a proportional change in wall thickness, with no changes in RWT. In contrast, isometric or static exercise involves developing muscular tension against resistance with little movement. Reflex and mechanical changes cause a pressure load on the heart rather than a volume load resulting in a slightly enlarged ventricle with increased RWT hypertrophy.

**Effect of Obesity and Diabetes.** Obesity is associated with increased LV volumes, increased LVM, and most typically increased RWT. In the Framingham study, an increase of body mass index over time was closely related to increased LVM and volumes. Insulin resistance, metabolic syndrome, and diabetes mellitus type II are similarly associated with increased LVM, RWT, and diastolic dysfunction. Diabetic patients have decreased systolic function as well. Correction of LVM for height preserves both the effects of obesity and elevated blood pressures on LVM. In contrast, correction of LVM for body surface area (BSA) effectively corrects for not only height but also obesity-related LV hypertrophy, which will remain undetected.

**Inherited and Ethnic Contributions.** Some of the variance in LV dimensions and mass may be explained by heredity, independent of the effects of sex, age, body size, blood pressure, heart rate, medications, and diabetes. Familial patterns of LV geometry were observed in subsequent generations of the Framingham study, but not in spouses. The greatest inheritable risk was found for concentric remodelling.

Normal ranges of LVM differ across races, being larger in African-Americans than in white Americans and/or Hispanics and smaller in Asian-Americans. Within one ethnicity, differences also exist between populations, e.g. Scandinavians being different from Mediterraneans. Only a part of these differences is accountable to ethnic variation in body size, and can be corrected by scaling. It is still unclear to what extent ethnic differences prevail when scaling for fat-free mass. It remains to be clarified to what extent these ethnic differences are related to increased LVM and LVMc across all covariates. Therefore, normal ranges of LVMc per BSA and include 34 mL/m². As with the LV, scaling by BSA corrects for obesity-related LVM, or for height. In the endstage hypertensive heart, there is an increase in LVM and sparcity, a decrease in stroke volume, and finally a reduction in EF.

**LV Hypertrophy Due to Increased Load.** Two basic patterns of cardiac hypertrophy occur in response to haemodynamic overload. In pressure overload (e.g. hypertension), pressure elevation most commonly leads to an increase in wall thickness and RWT, a phenomenon known as concentric remodelling (see the Identification of LV Geometric Patterns section). Eventually, an increase in systolic wall stress leads to concentric hypertrophy, caused by the addition of sarcomeres in parallel (hence, widening the cardiac myocytes), an increase in myocyte cross-sectional area, and an increase in LV wall thickening. In the Framingham Heart study, hypertensive patients had a greater increase in LVM and volume, and a smaller age-related reduction in LV size than individuals with normal blood pressure. In contrast, eccentric hypertrophy due to volume overload (e.g. with mitral regurgitation) is caused by increased diastolic wall stress. This leads to an increase in myocardial wall thickness with the addition of sarcomeres in series (hence, lengthening of cardiac myocytes), thereby engendering LV enlargement.

**Adaptation of LV Function to Increased Load**

The complex changes that occur in the heart during LV remodelling cause alterations in LV size and geometry, but the process of LV remodelling also leads to alterations in contraction and relaxation, the volume of myocyte and non-myocyte components of the myocardium, the properties of the myocyte (sarcomeres, e.g. titin), and the extracellular matrix (balance of collagen types I and III, and collagen fraction). Diastolic function is influenced by alterations in LV systolic function and geometry, delayed myocardial relaxation, increased passive stiffness of the sarcomere and extracellular matrix, and altered myocardial tone.

Cardiac myocyte hypertrophy leads to foetal gene reactivation and increased expression of a number of genes normally expressed in the adult heart. Depending on age, sex, duration of hypertension, severity, and treatment, differing cellular and molecular events may underlie the evolution from a ventricle with concentric hypertrophy to a more dilated failing ventricle (often presenting as HFpEF, heart failure reduced ejection fraction) or to a heavily fibrotic and non-dilated ventricle (presenting as HFrEF, heart failure preserved ejection fraction), according to the three stages in the hypertrophic process (overload, hypertrophy, and failure). Physiological hypertrophy (growth, pregnancy, and exercise) is characterized by normal organization of cardiac structure and normal or enhanced cardiac function, whereas pathological hypertrophy is commonly associated with upregulation of foetal genes, fibrosis, cardiac dysfunction, and increased mortality. The continuous vs. intermittent nature of overload in the settings of pathological and physiological hypertrophy is unlikely to account for the differences in response. In contrast to early-systolic load, late-systolic load delays myocardial relaxation and induces more maladaptive hypertrophy.

**Morphology of the Hypertensive Heart**

**LV Morphology.** LV hypertrophy is defined on a normative basis; a definition based on 2 SD above the mean LVM in the general population will differ from a definition based on the healthy population without obesity or hypertension. Separate cutoffs are required for men and women. If LVM is corrected for BSA, it should be recognized that this corrects for obesity-related LVM, or for height. In the endstage hypertensive heart, there is an increase in LV volumes and sparcity, a decrease in stroke volume, and finally a reduction in EF.

**LA Morphology.** Left atrial (LA) volume may be calculated by either area-length or modified Simpson’s methods, and is usually scaled for BSA and expressed in mL/m²; the normal range is up to and including 34 mL/m². As with the LV, scaling by BSA corrects for obesity-related increase in LA size that as a consequence will remain undetected. The LA is not symmetrical, and enlargement may occur non-uniformly, predominantly in one direction. Consequently, LA size is much better evaluated with 2D- or 3D-based LA volume rather than with M-mode. In hypertension and other situations where diastolic dysfunction occurs, reduction in early diastolic emptying is compensated by forceful atrial contraction. In addition, intermittent or permanent elevation of LA filling pressures leads to overfilling of the LA. The resulting LA enlargement is the ‘morpho-physiologic expression’ of chronic diastolic dysfunction, hypothesized to reflect the duration and severity of increased LA pressure. Although the presence of atrial fibrillation itself contributes to atrial size, LA enlargement is a well-known independent determinant of stroke, cardiovascular events, and death. Moreover, atrial fibrillation may be another endpoint of this process, predisposing to atrial remodelling and dysfunction with atrial fibrillation. This is a common endpoint that may be initiated by a number of aetiologies, including hypertension and diabetes mellitus.
The main determinants of an increasing atrial size with age are the cardiovascular risk factors of elevated blood pressure and obesity.31 In hypertensive patients, LA enlargement is related to LVM (rather than the type of LV hypertrophy), overweight, higher fasting glucose, and metabolic syndrome.32

MEASUREMENT OF LVM

Linear Echocardiographic Dimensions

Acquisition and Measurements. The measurement of LVM requires accurate measurements of wall thickness and chamber dimensions, as described in the Chamber Quantification update.29 The linear measurements of LV internal dimension (LVIDd), septal (IVS), and PW are made from the parasternal long-axis acoustic window at the level of the LV minor axis, approximately at the mitral valve leaflet tips. M-mode recordings have excellent temporal resolution, and may be chosen from 2D images. However, even when directed by 2D guidance, it may not be possible to align the M-mode cursor perpendicular to the long axis of the ventricle (Figure 2). Software has been developed to reconstruct anatomical M-mode images from 2D images (Figure 3), but this is not yet universally available. Reference normal values for LV linear measurements are published in the Chamber Quantification update.29 Alternatively, chamber dimension and wall thicknesses can be acquired from the parasternal short-axis view using direct 2D measurements. The use of 2D-derived linear dimensions overcomes the common problem of oblique parasternal images resulting in overestimation of cavity and wall dimensions from M-mode (Figure 4).

When 2D measurements are used, the wall thicknesses and linear dimensions should be measured at the level of the LV minor dimension, at the mitral leaflet tips level. The upper limit of normal for LVIDd is smaller than the M-mode measurement. Left ventricle internal dimension diastole (LVIDd), inter-ventricular septum diastole (IVSd), and posterior wall diastole (PWd) are measured at end-diastole from 2D or M-mode recordings, preferably on several beats. Understanding the LVM literature is facilitated by recognizing various methods:

i. The original American Society of Echocardiography (ASE) approach recommended that dimensions be measured from the leading edge to the leading edge of echocardiographic borders. This results in the inclusion of endocardial echoes from the IVS and PW, and the exclusion of endocardial echoes from the LVIDd.33 This was because the trailing edge of endocardial signals is dependent on gain settings. This may impact on LVM measurements, especially at the upper and lower extremes of these measurements.34 The simplified calculation of LVM with this approach is LVM = 1.04[(IVS + LVIDd + PW)³ / LVIDd³] + 0.6 g.

ii. The subsequent Penn convention excluded endocardial echoes from IVS and PW dimensions, but included endocardial echoes in measurement of the LVIDd.35 As the Penn convention gives larger cavity dimensions and smaller wall thicknesses than the ASE convention, the use of this approach necessitates subtraction of 13.6 from the previous mass calculation.

iii. The current ASE/European Association of Cardiovascular Imaging (EACVI) Chamber Quantitation Guidelines point out that refinements in image processing have allowed measurement of the actual visualized thickness of the ventricular septum and other chamber dimensions as defined by the actual tissue–blood interface, rather than the distance between the leading edge echoes, which had previously been recommended (Figure 5).29

All LVM algorithms (M-mode, 2D, or 3D echocardiographic measurements) are based on subtraction of the LV cavity volume from the volume enclosed by the LV epicardium to obtain the volume of the
shell between the LV cavity and the epicardial surface. This shell volume is then converted to mass by multiplying LV wall volume by the specific gravity of myocardium (1.05 g/mL). The formula used for estimation of LV mass from LV linear dimensions is based on modelling the LV as a prolate ellipse, and assumes that the major/minor axis ratio is 2 : 1: LVMM = \(0.8 \times \frac{(1.04(LVIDd + PW + IVSd)^3 - (LVIDd)^3)}{C0}(LVIDd)^3\) + 0.6 g. Extensive validation of this formula has been performed from necropsy specimens.36

**Normal Values.** Table 1 summarizes the reported range of normal values for LV mass by M-mode echocardiography.3,17-45 These values differ between men and women, with the latter systematically lower than the former, even when indexed for BSA (Table 1; see the section below—methods of indexation). The upper limits of normal ranges in the ASE chamber quantification update are >95 g/m² (>44 g/ht².7) in women and >115 g/m² (>48 g/ht².7) in men.29

**Limitations.** There are four principal limitations in the calculation of LV mass using linear methods:

i. The ‘Cube’ formula is not accurate in patients with major distortions of LV geometry (e.g. apical aneurysm, or any condition where the 2 : 1 axis ratio requirement is not met).

ii. Because this formula involves cubing primary measurements, even small errors in these measurements may be magnified.

iii. These measurements are insensitive to small changes in mass.

iv. The measurements are highly dependent on imaging quality and observer expertise.

**Two-Dimensional Echocardiography**

The most commonly used 2D methods for measuring LV mass are based on the area-length formula and the truncated ellipsoid model, as described in detail in the previous ASE/EACVI chamber quantification document46 (figure 6). In the presence of shape distortions, such as that caused by post-myocardial infarction (MI) remodelling, the geometric assumptions inherent in this approach remain problematic. Both methods were validated in the early 1980s in animal models and by comparing premorbid echocardiograms with measured LV weight at autopsy in human beings. Normal values are summarized in Table 2,47,48 and the degrees of abnormality are classified in Table 3. The main limitations relate to image quality and the temporal resolution of 2D imaging, compared with...
M-mode echocardiography. The limitations of M-mode regarding geometrical assumptions and the impact of small error on measurements are also applicable to 2D measurements. In addition, 2D imaging leads to frequent foreshortening due to inappropriate cut-planes.

Three-Dimensional Echocardiography

The benefit of three-dimensional echocardiography (3DE) is especially to obviate inaccurate geometric assumptions, inherent to 2DE, that become exaggerated in remodelled ventricles. 3DE is a potentially attractive modality for the measurement of LVM, and normal ranges have been developed.49 The accuracy of 3DE is reportedly similar to cardiac magnetic resonance (CMR) imaging methods for measuring LVM.50-52 However, there are wide limits of agreement which primarily relate to difficulties in accurately tracing the LV epicardial border, particularly in dilated ventricles,53 and generally show that while 3DE is imperfect for LVM estimation—with a tendency to underestimate LVM compared with CMR imaging in patients with cardiac disease—the accuracy is more favourable than with alternative ultrasound methods. Normal values of M-mode, 2D mass, and 3D mass are given in Tables 1 and 2. Degrees of abnormality of LVM are summarized in Table 3 and the validation of all methods against reference techniques is summarized in Table 4. A later section describes the use of 2D and 3D for the assessment of LV function.

Recommendations

LVM is prognostically important and should be reported in hypertensive patients. In the normally shaped LV, either M-mode or 2DE formulas can be used to calculate LVM. The majority of community-acquired prognostic evidence has been gathered with M-mode imaging.

In laboratories that use 3DE routinely, 3D LVM measurement should be considered—especially in abnormally shaped ventricles or in individuals with asymmetric or localized hypertrophy. 3DE is the only echocardiographic technique that measures myocardial volume directly, without geometric assumptions about LV shape and distribution of wall thickening.

Identification of LV Geometric Patterns

While patients with early hypertensive disease will most likely have normal LV geometry, longstanding or untreated hypertension will result in changes in LV shape and eventually, a deterioration of systolic function. Broadly, the changes in LV geometry can be classified according to whether LVM is normal or increased and whether ventricular morphology (RWT) is altered.46 RWT is variably reported as (PW * 2)/LVd or (IVS + PW)/LVd, of which we favour the former because septal measurements may be confounded by the presence of septal bulge. RWT is problematic and not reflective of true LV geometry in patients with asymmetric hypertrophy. The upper limit of normal RWT is 0.42.29

CHS healthy subgroup: no prevalent HF, CVD, hypertension, obesity, or subclinical heart disease (i.e. normal aortic augmentation index and normal carotid intima-media thickness).
Concentric LV Hypertrophy

Concentric LV hypertrophy, probably most commonly associated with hypertension, is characterized by normal cavity size, uniformly increased LV wall thickness, and increased LV mass (Figures 7 and 8).46 Cutoff values adopted by the ASE and EACVI are based on either overall LV mass (g), LV mass/BSA (g/m²), LV mass/height (g/m), or LV mass/height² (g/m²) and while each has been shown to have limitations of either under- or overestimating LVM, each has been used successfully in characterizing LV hypertrophy in different patient populations.

Concentric LV hypertrophy is an adaptive response to high systemic pressure caused by hypertension or diseases such as aortic stenosis, coupled with high peripheral resistance. Concentric LV hypertrophy (LVH) and changes in LV geometry have been shown to affect both men and women regardless of age,55 and are also associated with changes in diastolic function, longitudinal and radial myocardial function, and atrial size.56-58

Eccentric LV Hypertrophy

In contrast to concentric LVH, eccentric hypertrophy is associated with volume, rather than pressure overload. This is usually due to significant valvular regurgitation or high cardiac index, as is seen in elite athletes (although concentric hypertrophy may be the consequence of strength training). Systemic pressure is normal and peripheral resistance is not increased in patients with eccentric hypertrophy. Echocardiographic findings show increased LV cavity size, normal LV wall thickness, and increased LVM (Figure 9). Patients with eccentric hypertrophy share similar changes in diastolic function and longitudinal and radial function as those with concentric hypertrophy.55,57,58 Unlike concentric hypertrophy, however, patients with eccentric LVH generally have low normal or mildly impaired systolic function due to chronic volume overload.

Changes in LV shape associated with LV enlargement have been quantified as sphericity index. This is a ratio between measured end diastolic volume (EDV) (preferably with 3DE) and a spherical volume based on the longitudinal dimension of the LV (4/3 × π × D²/2).2 This parameter has been shown to be a predictor of remodelling, but this is more in the setting of LV dysfunction after MI than in hypertensive heart disease.59

Concentric Remodelling

Concentric LV remodelling is a late stage response of the LV and can be caused by chronic pressure, volume overload, or MI. It is most commonly associated with coronary artery disease, but is also associated with longstanding hypertension, especially untreated hypertension.60 Like eccentric hypertrophy, it is also associated with LV systolic dysfunction. Echocardiographic features show normal or small LV cavity size, usually increased LV wall thickness and normal LVM (Figures 7 and 10). Concentric remodelling is also associated with changes in the shape of the LV—e.g. LV sphericity changes—and becomes more rounded, rather than bullet shape. The result of this is more dramatic degradation of diastolic function and loss of radial and longitudinal function.57
Hypertension is diastolic dysfunction. This can be detected as tension, LVH is usually absent and the first manifestation of volume overload seen in valvular disease. However, in early, mild hypertension, LVH develops as an adaptive response to chronic pressure, and more severe disturbances of diastolic filling occur and left ventricular systolic function will become impaired. Eventually, LV remodelling will occur and left ventricular systolic function will become impaired. While the goal of hypertension management is to prevent any changes in LV geometry, the current ability of echocardiography to provide serial assessment of the LV response in the individual patient is compromised by variability of LV volume measurement.

The haemodynamic disturbances and humoral stimulation that lead to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV volume and function addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV volume and function addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel.

### Table 3 Degrees of abnormality of LVM

| Women | | |

### Other Classification

The limitation of the classical categories is the suboptimal categorization of dilated ventricles. Recently, Gaasch and Zile proposed a subdivision based on LV volume (vertical axis), LV volume (horizontal axis), and RWT or M/V, represented by the oblique lines indicating the upper (full) and lower (dashed) limit of normality (Table 6 and Figure 7). Using this approach, the non-dilated ventricle is characterized as having normal morphology, concentric remodelling, or concentric hypertrophy, based on LVH and RWT (>0.42). Dilated ventricles without LVH are described as having eccentric hypertrophy (RWT <0.32), mixed hypertrophy (RWT >0.42), or physiological hypertrophy (RWT 0.32–0.42). The resulting categories yield distinct functional behaviours and prognoses.

### Natural History of LV Geometry in Hypertension

Left ventricular hypertrophy is caused by increased wall stress, either due to chronic pressure overload, as seen in hypertension, or the volume overload seen in valvular disease. However, in early, mild hypertension, LVH is usually absent and the first manifestation of hypertension is diastolic dysfunction. This can be detected as grade I diastolic impairment, or impaired relaxation. Over time however, if left untreated, filling pressures continue to rise, ventricular hypertrophy develops as an adaptive response to chronic pressure, and more severe disturbances of diastolic filling are more commonly encountered. Eventually, LV remodelling will occur and left ventricular systolic function will become impaired.

### Tissue Characterization

The haemodynamic disturbances and humoral stimulation that lead to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV volume and function addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel. While measurement of LV volume and function addresses the response to the cardiac responses to hypertension do not necessarily progress in parallel.
to haemodynamic disturbance, this may not necessarily reflect the full physiological impact of hypertension on the heart. While not part of current guidelines, tissue characterization may provide information about myocardial remodelling and allow targeted therapy against molecular changes, sarcoplasmic failure, apoptosis, fibrosis, and disturbances of vascular structure and function.65 Interstitial, perivascular, plexiform, and replacement fibrosis of necrotic tissue66 are likely responsible for disturbances of myocardial perfusion, synchrony, and rhythm.

An important reason for attempting to characterize myocardial tissue is that not all increments in LV mass occur in the setting of hypertensive heart disease are due to hypertension. The recognition of other causes of increased wall thickness, including athletic hypertrophy, valvular disease, infiltrative disorders (amyloid, Friedrich’s ataxia, and Fabry’s disease), non-compaction, and hypertrophic cardiomyopathy,65 have important treatment implications.

Measurements performed using 2D-directed M-mode.29

ARTERIAL FUNCTION AND VENTRICULO-ARTERIAL MATCHING

Arterial Function

Arterial Afterload. Arterial afterload is characterized by both steady and pulsatile components of blood pressure.79 This parameter is determined by impedance, compliance, or resistance, derived from aortic pressure ($P_a$) and flow waveforms ($F_a$), both of which can be assessed non-invasively by means of applanation tonometry and ultrasound, respectively.

A variety of measurements have been created to better understand the process of displacement of blood from the LV into the arterial tree (Figure 11). If the arterial system was composed of rigid tubes without any storage capacity, blood would be accelerated in systole throughout the complete arterial tree, which would give rise to very
large intra-arterial pressure differences (and a high load on the heart). Owing to the elasticity of the large arteries, however, part of the stroke volume is locally stored in the aorta in systole (the ‘windkessel’ function), buffering the pulsatility of blood flow and providing a more continuous blood flow in the distal circulation. This reduces the importance of inertial forces. Characteristic impedance (Zc) reflects the interplay between these inertial effects and the local storage of blood in the proximal aorta and the load initially experienced by the ventricle upon opening of the aortic valve. It is calculated by plotting the relation of time-varying $P_{ao}$ (aortic pressure) vs. time-varying $F_{ao}$ (aortic flow) during the ejection phase of the cardiac cycle; the slope provides Zc [in mmHg/(mL/s)]. This parameter is dependent on blood pressure and aortic size; a stiff and narrow aorta leads to high Zc, a distensible, wide aorta to a low Zc. While Zc determines the upstroke of pressure, pulse pressure is mainly determined by the total arterial compliance (TAC) of the arterial tree in combination with the systemic vascular resistance (SVR). The simplest approximation of TAC is the ratio of the stroke volume and pulse pressure (mL/mmHg), although this leads to systematic overestimation. TAC is highly size-dependent, depends non-linearly on arterial pressure, and that there are systematic differences between different methods, making TAC a parameter difficult to standardize (Figure 11).

**Arterial Afterload: Pulse Wave Velocity and Wave Reflection.** The above section simplifies the arterial system to a simple ‘windkessel’ system. Cardiac contraction gives rise to pressure- and flow waves travelling through the arterial tree. The stiffer the arteries, the higher the pulse wave velocity (PWV; Figure 12). PWV is proportional to the intrinsic mechanical properties of the arterial wall (stress–strain relationships), the ratio of wall thickness to lumen diameter, and inversely proportional to the density of blood (which is virtually constant). Thus, PWV is independent of size and only varies with arterial remodelling or changes in arterial tissue properties (note that these are pressure-dependent). The carotid and femoral artery is the most commonly used measuring locations, with time delay derived from either pressure (tonometry), ultrasound- (pulsed Doppler), or CMR-based (phase contrast) signals. As the carotid and femoral artery is not along a single unequivocal trajectory, the latest consensus is that distance is approximated as 0.8 times the linear distance measured directly between the carotid and femoral sites. Age-specific normal values for carotid–femoral have been reported (Figure 13), but have the disadvantage of obscuring the important effect of age. Numerous studies have now demonstrated an association between increased arterial stiffness and increased cardiovascular risk. Although PWV provides an overall estimate of the elastic
properties of the aorta and central arteries, it also depends on functional and dynamic properties, including production of nitric oxide. It is also possible to assess the local elastic properties at the carotid or femoral artery, and several ultrasound-based techniques exist for this purpose (e.g. wall tracking to measure arterial distension) or are under investigation (pulse wave imaging and shear wave imaging).

Wave dynamics are too complex to resolve in full detail in an *in vivo* setting and are commonly simplified, considering only one forward (generated by the heart) and one backward wave (due to reflections in the periphery). The timing and magnitude of these waves can directly be linked to cardiovascular pathophysiology. Recent studies have reported an association between augmentation index (a rather poor measure of wave reflection) and cardiovascular risk, although there is disagreement about the prognostic value of this information. An increased magnitude of wave reflection, measured with the wave decomposition technique, is an independent prognostic determinant of cardiovascular risk and a powerful and independent predictor of incident heart failure.

### Ventriculo-Arterial Interaction

#### The Classical Approach to Ventriculo-Arterial Matching

The most widespread paradigm for the assessment of ventricular–vascular coupling is the ventricular (Ees)–arterial (Ea) elastance framework, which links mechanical performance of the ventricle to its oxygen consumption.

For an efficient energy transfer, the LV should develop an elastance that is greater than the arterial elastance. Arterial elastance is commonly calculated as end-systolic pressure/stroke volume and is a measure of resistive, not pulsatile load. Ees is the end-systolic elastance (slope of the end-systolic pressure–volume relation), a measure of ventricular contractility. Ea stands for arterial elastance (ratio of end-systolic pressure and stroke volume), although it is an imperfect measure of arterial properties, being highly sensitive to the heart rate. Resting Ea/Ees ratios of ~0.62–0.82 are observed across species and in human populations. The LV generates maximal stroke work when Ea/Ees = 0.80, while it operates at maximal energetic efficiency with an Ea/Ees of 0.70. The normal Ea/Ees values seen in the Asklepios cohort and the Olmsted cohort suggest that normal subjects’ Ea/Ees values approximate this optimal value. Values >1 indicate an ’ill-matched’ ventricle and arterial system. While the framework is essentially based on pressure–volume loop analysis—and hence restricted to an invasive setting—it has been simplified to make it suitable for application in clinical settings, approximating Ees as the ratio of end-systolic pressure and stroke volume (ESV) or via the use of single-beat methods that take advantage of the relatively small variability in the shape of the normalized time-varying left ventricular elastance curve over the cardiac cycle.

#### Novel Approaches to Ventriculo-Arterial Matching

The standard Ea/Ees analysis does not involve any evaluation of time in the analysis. Using cardiac ultrasound and applanation tonometry (Figure 13), myocardial stress can be expressed as a function of time throughout systole. Peak stress occurs in early systole, before important contributions of reflected waves to central pressure and correlates directly with SVR and Zc. The greater peak and end-systolic wall stress and higher ejection phase stress-time integral in women may relate to the susceptibility of women to heart failure.

Wave intensity analysis is a new method of assessing ventriculo-vascular interaction. There are three aortic waves: (i) a wave reflecting LV contraction, generating a forward wave increasing pressure and...
flow; (ii) a reflected wave, generally increasing pressure and lowering blood flow, and (iii) a late-systolic wave due to LV relaxation, lowering blood pressure and flow. Current research is seeking whether this wave-based analysis can be used to quantify cardiac systolic and diastolic performance.

Assessment of the Aorta
Hypertension is an important contributor to aortic disease, and any echocardiogram performed for the evaluation of end-organ disease should include assessment of the aorta. Echocardiographic views are usually limited to the ascending aorta between the coronary sinuses and main pulmonary artery, the aortic arch (in the suprasternal view), the descending aorta in the far-field of the parasternal, suprasternal, and foreshortened apical two-chamber view, and the abdominal aorta in the subcostal view. In particular, this simple step adds an incremental value in screening men >65–70 years old for abdominal aortic aneurysm, especially if they are smokers. Coarctation of the aorta is a well-known structural abnormality that can lead to hypertension and LV hypertrophy and may go undetected by clinical assessment, particularly in younger adults. The echocardiogram is central to making this diagnosis, so younger patients presenting with hypertension should undergo 2D imaging, colour and Doppler assessment of the distal arch and upper descending aorta. Further information about echocardiography and aortic disease, including normal aortic dimensions, are described in the EACVI recommendations for clinical practice.90

Recommendations
Blood pressure should be obtained at the time of the examination and integrated into the report.
Aortic dimensions should be reported in all studies of hypertensive subjects.
Measurement of pulse wave velocity should be considered as a marker of vascular health and risk in primary prevention patients.
Assessment of ventriculo-arterial mismatch is currently a research rather than a routine clinical investigation.

LV SYSTOLIC FUNCTION IN HYPERTENSION
Parameters from Linear Measurements
LV linear dimensions for the calculation of LVM are widely used in the setting of hypertensive patients. The use of these measurements for the evaluation of endocardial fractional shortening (FS) has been superseded by more accurate and reliable measures. Likewise, the Teichholz or Quinones methods for measurement of EF from linear measurements are dependent on geometric assumptions and are not recommended.
Two-Dimensional Measurements

While the process of tracing LVM (above) and volumes are similar, the prognostic independence of LVM and function justifies their separation. The techniques and reference normal values for obtaining EF from tomographic 2D echocardiography are summarized in the Chamber Quantification update. The biplane method of discs (modified Simpson’s rule obtained from apical four- and two-chamber views) is the most accurate in abnormally shaped ventricles. In the pre-harmonic and pre-digital era, the main sources of inter-study variability included repeated echo recordings, repeated video measurements, and measurements made by different investigators. Similar analyses have not been performed by harmonic imaging, which may be an important distinction for two reasons. The use of lower frequencies (required for the creation of a wider broadband) implies a reduction of spatial resolution, with apparently thicker structures and potential effects on the measurement of wall thickness. On the other hand, the use of harmonic imaging improves the reproducibility of 2D LV volumes.

Three-Dimensional Measurements

Assessment of LV volumes by 2DE is limited by foreshortening, mal-rotation, angulation, and a reliance on geometric assumptions for volumetric calculation, resulting in an underestimation of the true volumes, particularly in remodelled ventricles. When compared with CMR, 2D determination of LV volumes shows higher inter-study variability which reaches statistical significance for LV ESV (4.4–9.2% vs. 13.7–20.3%, P < .001). and results in higher calculated sample sizes (increases of 55–93% in comparison with CMR) to show clinically relevant changes in LV size.

The ejection phase indices (FS, EF, stroke volume, and cardiac output) cannot determine the relative contribution of each of these variables to LV pump function. In particular, load dependency of these parameters may induce inaccurate estimation of intrinsic myocardial contractility in chronic pressure overload conditions. The estimation of LV afterload may help in determining whether or not observed LV pump function is representative of actual myocardial contractile performance. The most direct measurement of LV afterload is end-systolic stress (ESS). Two main types of ESS can be measured, meridional and circumferential ESS (cESS), each acting as counter forces to fibre shortening.

Three-Dimensional Measurements

Assessment of LV volumes by 2DE is limited by foreshortening, mal-rotation, angulation, and a reliance on geometric assumptions for volumetric calculation, resulting in an underestimation of the true volumes, particularly in remodelled ventricles. When compared with CMR, 2D determination of LV volumes shows higher inter-study variability which reaches statistical significance for LV ESV (4.4–9.2% vs. 13.7–20.3%, P < .001). and results in higher calculated sample sizes (increases of 55–93% in comparison with CMR) to show clinically relevant changes in LV size.

The ejection phase indices (FS, EF, stroke volume, and cardiac output) cannot determine the relative contribution of each of these variables to LV pump function. In particular, load dependency of these parameters may induce inaccurate estimation of intrinsic myocardial contractility in chronic pressure overload conditions. The estimation of LV afterload may help in determining whether or not observed LV pump function is representative of actual myocardial contractile performance. The most direct measurement of LV afterload is end-systolic stress (ESS). Two main types of ESS can be measured, meridional and circumferential ESS (cESS), each acting as counter forces to fibre shortening.

Longitudinal shortening of endocardial fibres is limited by longitudinal (meridional) ESS, which can be measured using a catheterization-validated formula which incorporates end-systolic LV internal diameter (LVIDs) and wall thickness coupled with simultaneous cuff blood pressure.

Three-Dimensional Measurements

Assessment of LV volumes by 2DE is limited by foreshortening, mal-rotation, angulation, and a reliance on geometric assumptions for volumetric calculation, resulting in an underestimation of the true volumes, particularly in remodelled ventricles. When compared with CMR, 2D determination of LV volumes shows higher inter-study variability which reaches statistical significance for LV ESV (4.4–9.2% vs. 13.7–20.3%, P < .001). and results in higher calculated sample sizes (increases of 55–93% in comparison with CMR) to show clinically relevant changes in LV size.

The ejection phase indices (FS, EF, stroke volume, and cardiac output) cannot determine the relative contribution of each of these variables to LV pump function. In particular, load dependency of these parameters may induce inaccurate estimation of intrinsic myocardial contractility in chronic pressure overload conditions. The estimation of LV afterload may help in determining whether or not observed LV pump function is representative of actual myocardial contractile performance. The most direct measurement of LV afterload is end-systolic stress (ESS). Two main types of ESS can be measured, meridional and circumferential ESS (cESS), each acting as counter forces to fibre shortening.

Longitudinal shortening of endocardial fibres is limited by longitudinal (meridional) ESS, which can be measured using a catheterization-validated formula which incorporates end-systolic LV internal diameter (LVIDs) and wall thickness coupled with simultaneous cuff blood pressure.
A recent meta-analysis of validation studies comparing 3DE and CMR demonstrated that considerable variability still exists in the measurement of LV volumes (± 34 mL for EDV, ± 30 mL for ESV, and ± 12% for EF), although it is less than that observed between 2DE and CMR. Moreover, both 2DE- and 3DE-derived volumes are less accurate in dilated LVs. Several sources of 3D volume acquisition and measurement error are discussed in the recent ASE/EACVI guidelines, including difficulty in imaging the anterior and lateral walls because of interference from ribs, low line density (and therefore lower spatial resolution—which may be partly readdressed with the use of LV opacification), low temporal resolution (which may be addressed by using multiple subvolumes—but at the risk of stitching artefacts), and time-consuming off-line analysis. Recently, a fully automated endocardial contouring system combined with real-time full-volume 3DE has been described as providing accurate and reproducible volumes.

Midwall Function

Rationale. LV systolic function is commonly assessed through the use of EF and FS. However, because these measurements are performed at the endocardial surface, their appropriateness has been questioned in patients with LV hypertrophy. The inner layer of the LV has been shown to move inward further than the outer layer, a difference markedly increased in hypertrophic walls due to the 'cross-fibre shortening' phenomenon which, in hypertrophic LVs, achieves normal systolic wall thickening despite reduced shortening of individual myocardial segments. Hence, LVEF and FS often lead to overestimation of LV systolic performance yielding normal or even supranormal results not matching the individual’s clinical situation and prognosis, since they take into account geometric changes that do not accurately reflect the actual contractile function of the myocardium. The greatest proportion of ventricular myocardial fibres is located in the myocardial midwall, the region responsible for circumferential left ventricular contraction and where cross-fibre shortening is less significant. Consequently, indices representing LV midwall mechanics have received increasing attention lately, as they have shown to better reflect myocardial contractile status in patients with LV hypertrophy.

A variety of parameters have been used to assess LV midwall function. Midwall FS (FSmw) has been the most widely used. Based on M-mode measurements, calculation of FSmw is generally calculated following the model described by Shimizu et al. based on the assumption of a cylindrical-shaped LV resulting from the union of two concentric cylindrical shells of equal end-diastolic thickness and on the fact that LVM does not vary throughout the cardiac cycle. This model allows FSmw to be calculated through the following formula:

\[ cESS = \frac{(SBP/C2)(LVIDd/2)^2}{(1 + (LVIDd/2 + PWd/2)^2/(LVIDd + IVSd/2 + PWd/2)^2)} \]

where SBP represents systolic blood pressure. This correction has shown to discriminate hypertensive from physiological LV hypertrophy in athletes.

Validation and Normal Values. Several studies have provided a reference of normal absolute and stress-corrected FSmw values in healthy populations. Mean normal values in these studies range from 17 to 21%, with no observed differences with gender and ethnicity, and while most studies have pointed out a slight decrease in FSmw with age, these may be due to subclinical...
Tissue Doppler Assessment of Systolic Function

Tissue Doppler was the first widely available myocardial imaging technique, and is credited with improving the feasibility of longitudinal ventricular function measurement. Several studies have shown tissue Doppler—using either pulsed-wave or colour mapping—to be a reliable tool for the assessment of LV systolic function. This method has been validated against other methods for the assessment of myocardial systolic performance and regional coronary blood flow, as well as with histological findings. Its high temporal resolution enables accurate determination of myocardial velocity and acceleration even when overall image quality is deficient and endocardial delineation is poor. Technical considerations related to tissue Doppler have been considered in several clinical scenarios, through better prediction of cardiovascular outcomes than indices based on endocardial measurements and better correlation with patients’ clinical status.

Limitations. Some of the limitations of midwall function assessment include the fact that FSmw is based on a limited region of the LV, which could hinder its application to patients with variable LV geometries. Another potential limitation is the need for manual tracking, which introduces the problems of time-consuming analysis and potential interobserver variability. However, new indices and calculations partly overcome these limitations through the analysis of 2D and 3D midwall mechanics, introducing the concepts of 2D and 3D midwall EF. Finally, advanced echocardiographic techniques are modifying the understanding of the hypertensive heart. Disturbances of longitudinal strain of the endocardial layer precedes the alteration of circumferential strain, which is attributed to the midwall layer. This is important because LV longitudinal dysfunction plays a role in mediating the effect of LV geometry on LV diastolic impairment.

conditions and have shown no statistical significance in some series in which the study population was screened to rule out cardiovascular disease.

The study of midwall mechanics has shown to be superior to other conventional echocardiographic indices of LV systolic function in several conventional scenarios, through better prediction of cardiovascular outcomes than indices based on endocardial measurements and better correlation with patients’ clinical status.

The recommended Doppler velocity range is usually ±15–20 cm/s, but can be adjusted to the lowest possible without generating aliasing. The main parameter for systolic performance that can be extracted from tissue Doppler evaluation is E’, which can be identified as a wave signal in the direction of the apex and initiated immediately after the QRS complex. Among tissue Doppler parameters, E’ has shown the best correlation with LVEF and significant clinical outcomes such as rehospitalization and reduced survival, although measurements at the septal and lateral side in the apical four-chamber view have proved to produce good results (E’ < 7 cm/s showing 93% sensitivity and 87% specificity to identify patients with LVEF < 45%). Other authors have reported slightly higher diagnostic power with measurements at six sites from the apical four-chamber, two-chamber and long-axis views (six-site average E’ > 5.4 cm/s showing 88% sensitivity and 97% specificity for LVEF < 50%).

In the setting of hypertensive patients, tissue Doppler measured E’ helps differentiate physiological LVH in athletes from hypertrophic cardiomyopathy, and the latter from LVH secondary to hypertension. Four-site measured mean E’ < 9 cm/s has shown to discriminate physiological from pathological LVH with a sensitivity of 87% and a specificity of 97%. Other studies have pointed out that hypertrophic cardiomyopathy patients have lower E’ values and higher heterogeneity than hypertensive LVH.

It is important to note that tissue Doppler relies completely on the detection of motion. This needs to be taken into consideration, since a potential limitation of this tool is the detection of myocardial motion occurring due to passive movement, such as swinging or tethering motion, instead of active myocardial contraction, potentially leading to either an over- or underestimation of LV systolic function. In addition, the use of deformation imaging in hypertensive heart disease has moved attention from midwall to longitudinal (and hence subendocardial) function. Impairment of longitudinal function always precedes the depression of LVEF in hypertensive patients, and may be a guide to the presence of fibrosis. Finally, tissue Doppler parameters are influenced by age and sex.

Assessment of Myocardial Function by Strain

Strain, strain-rate, and twist imaging (deformation imaging) are relatively recent non-invasive methods for the assessment of regional and global myocardial function, allowing discrimination between active and passive myocardial tissue movement. Assessment of strain and twist is extracted from images using the commercially available software, providing sensitive echocardiographic measures to detect early subclinical evidence of ventricular dysfunction. This information can be gathered using tissue Doppler echocardiography or

speckle tracking, and has been described in detail in a recent ASE/EACVI Consensus Statement. The measurement of strain has been well validated with sonomicrometry, three-dimensional tagged CMR, and cyclically compressed tissue-mimicking gelatin phantom. Among the different deformation (strain) components, longitudinal strain has gained an important value in this context. Longitudinal strain corresponds to the function of the endocardial layer of myocardium, where longitudinal fibres are subjected to the negative impact of early development of fibrosis in hypertensive heart disease. However, strain is highly sensitive to increased afterload, and the relative degree of impairment of strain that is due to LV dysfunction vs. that is due to hypertension may be difficult to tease apart. Reported normal values of global longitudinal strain vary from −15.9 to −22.1% (mean, −19.7%; 95% CI −20.4 to −18.9%).

This technique has been used to differentiate between different causes of increased wall thickness. In addition to the degree of reduction of strain, the pattern of strain reduction is also important. For example, amyloidosis is characterized by a particular pattern of apical sparing not seen in other causes of hypertrophy, and hypertrophic cardiomyopathy is associated with deformation disturbances at the site of hypertrophy with less abnormal deformation elsewhere. The morphology of the longitudinal strain signal may also be important in recognizing myocardial scarring. A characteristic double peak in the strain-rate signal has been identified in patients with scar tissue associated with hypertrophy in hypertrophic cardiomyopathy, Fabry’s disease, and aortic stenosis. This phenomenon presumably reflects a degree of post-systolic shortening in the presence of fibrosis. Thus, although the functional markers are non-specific for the diagnosis of hypertensive heart disease, they may demonstrate specific patterns and degrees of disturbance that distinguish between hypertensive hypertrophy and other aetiologies, as well as recognizing the contribution of fibrosis. Longitudinal strain can be even used to differentiate hypertensive heart disease from functional myocardial changes in the athlete’s heart.

Finally, CMR may be used for quantifying myocardial function, using techniques that measure myocardial deformation. It is not clear that these are superior to the echo techniques, as they are obtained at lower temporal resolution. This may be particularly pertinent for the identification of post-systolic shortening or disturbances of diastolic function.

Prognostic Significance of LV Function in Hypertension

Chamber Function. The prognostic significance of LV function is well established. It is known that heart failure is a common consequence of hypertension and in the majority of patients is related to impaired LV systolic function, which accounts for about half of heart failure cases. However, hypertension is not necessarily associated with a reduced systolic function—this may be increased in the initial stages. EF, a global measure of LV chamber function, is used to distinguish systolic (EF <50%) from diastolic HF (EF ≥50%), and is a reliable method for predicting primary cardiac events and cardiac mortality in individuals. Endocardial FS is a good measure of LV global systolic function; however, its use in the setting of hypertension is discouraged, especially in the presence of LV hypertrophy. As discussed above, both EF and FS are constrained because they measure endocardial function, whereas the true parameter of interest is midwall function. In addition, the limited field of view with M-mode leads to an under-appreciation of regional wall motion. Wall motion abnormalities can identify adults without known cardiovascular
prognostic importance of Doppler-derived LV filling is in patients with systolic HF, where mitral inflow measurements correlate with LV filling pressure, functional classes, and prognosis. In hypertension, normal in-treatment transmural flow pattern indicates a low risk for heart failure (HR 0.22 [95% CI 0.05–0.98, P = .048], independent of blood pressure. However, the intermediate ranges of E/A ratio (from 0.6 to 1.5) do not stratify prognosis in hypertensive subjects, probably because normal and pseudonormal patterns are combined. Although antihypertensive treatment in patients with LVH results in improvement of mitral inflow patterns, this was not associated with reduced cardiovascular morbidity and mortality.

Tissue Doppler Assessment of Myocardial Diastolic Function

Acquisition and Measurements. Guidance on the technical requirements for tissue Doppler acquisition has been provided regarding sample volume location, angulation, and respiratory phase. In hypertensive heart disease, early diastolic tissue velocity (e') is reduced by reduction in LV relaxation. However, it is also influenced by preload, systolic function, and LV minimal pressure. The other basic measured parameter is late (atrial) diastolic velocity (a'), influenced by LA function and LV end diastolic pressure. E/e' has been used as a measure of LA driving pressure or LV filling pressure. However, there are a number of situations where e' and E/e' may be misleading, including reduced septal e' velocity due to inferior infarction or annular calcification, and increased transmural E velocity due to mitral regurgitation. Averaging septal and lateral e' may reduce some of this variability, but does not address all of the limitations of the parameter.

Normal Values. Similar to mitral inflow velocity, e' values diminish with age (Table 7). For the evaluation of LV global diastolic function, it is recommended to record and measure tissue Doppler signals at both septal and lateral mitral annulus and obtain their average. The rationale of averaging septal and lateral values is derived from the observation that e' velocities are significantly greater at the lateral location than at the septal placement of the annulus. While single-site measurements can be used in the presence of globally normal or abnormal LV systolic function, the average of the two site measurements is particularly important in patients with LV regional dysfunction.

Prognostic Significance of Tissue Doppler Parameters

Annular tissue velocities are strong predictors of outcome in a variety of settings. In a 2-year follow-up study of >500 patients, 35% of whom had hypertension, Wang et al. showed that a pulsed-wave e' of <3 cm/s was associated with a 5.3-fold increment of hazard. As these data were gathered from colour-coded tissue Doppler, they represent unusually low values for e' velocities, analogous to pulsed-wave signals in the range of <5 cm/s. Similar findings have been described using an e' of <3.5 cm/s in hypertension and LV hypertrophy. It has to be acknowledged, however, that velocities <5 cm/s are quite extreme, and less usual in hypertensive heart disease than hypertrophic cardiomyopathy or infiltration.

Likewise, E/e' has prognostic implications, with E/e' ≥ 15 having been shown to add an independent prognostic value to B-type natriuretic peptide and EF. Although studies have been more focused on post-MI and heart failure than hypertension, Sharp et al. recently demonstrated the prognostic value of E/e' ratio in uncomplicated hypertensive patients, independent of LVM. On these grounds,
the 2013 ESC/ESH guidelines on arterial hypertension promote the use of E/e' in the detection of cardiac target organ damage in hypertensive heart disease.\textsuperscript{167}

**Recommendations**

All echocardiography reports in patients with hypertension should include specific comments about diastolic function grade, left atrial volume, and about normal vs. elevated LV filling pressure (usually based on E/e').

---

**CARDIAC IMPACT OF HYPERTENSION TREATMENT**

**LV Hypertrophy Regression**

LV hypertrophy represents an important end-organ consequence of hypertension. Population-based studies using echocardiography have demonstrated hypertrophy to be closely linked with adverse events,\textsuperscript{42,107} including stroke, renal impairment, left ventricular dysfunction, atrial and ventricular arrhythmias, and sudden cardiac arrest or premature death.\textsuperscript{169} The eventual development of complications from LVH represents long-term effects that are too final to guide clinical therapy, and too slow as a research outcome. Therefore, LVH has been proposed as a surrogate marker of outcome. LVH has been shown to be reversed or prevented by a variety of haemodynamic, non-haemodynamic, and pharmacological factors.\textsuperscript{169}

Nonetheless, the use of repeat imaging to document changes in LVM has been difficult to incorporate into standard practice for at least two reasons. The first relates to the inherent variability of LVM measurements with echocardiography. While reductions in the ventricular mass have been associated with improved outcome across populations, in studies which identify regression of hypertrophy on an individual basis, large populations are required to overcome the variability of these measurements. Thus, while the association between LVH regression and improved outcome has now been recognized in a number of studies,\textsuperscript{170} because of the test–retest limitations of echocardiography, CMR may be more accurate to demonstrate this effect.\textsuperscript{174} This role of echocardiography may be improved by the enhancement and clinical use of 3DE, which has been validated against CMR.\textsuperscript{178}

The second limitation is that hypertrophy occurs in 36–41% of hypertensive subjects,\textsuperscript{174} but hypertension is not the only cause of this problem. Hypertrophy may be influenced by obesity, diabetes, the metabolic syndrome, and renal impairment, among other etiologies. Progression of the condition may lead to ischaemia, both due to concurrent coronary artery disease as well as failure of vascular proliferation to match myocardial proliferation, vascular compression, and the effect of raised LV pressure on subendocardial flow.

**Change in LV Geometry**

Changes in LV geometry have been associated with improved blood pressure control, reflecting the impact of afterload on LV remodelling. Again, however, the variability of 2DE has been a limitation in understanding the association of reverse remodelling with improved survival, using conventional techniques. Recent evidence has indicated that use of CMR (or potentially 3DE) provides a means of measuring sphericity on a serial basis, and therefore documents remodelling changes in response to blood pressure control.

**Change in Systolic Function**

LV systolic function, measured by EF, is normally preserved until late in the course of hypertensive heart disease. Indeed, although EF is associated with outcome in patients with moderate LV impairment, the association of mild or borderline impairment with adverse outcome has been more difficult to show. Likewise, volumetric and EF changes in heart failure have been associated with improvements in outcome.\textsuperscript{172,173} but this information is difficult to apply to hypertensive heart disease in which EF is either preserved or borderline reduced.

**Change in Diastolic Function**

Diastolic dysfunction, particularly in the later stages of hypertensive heart disease, is associated with prognosis.\textsuperscript{174} However, most patients with hypertensive heart disease have grade I diastolic dysfunction, and changes in this finding are intrinsically ambiguous. When the E/A ratio is <1 and moves towards unity, this may occur because of recovery of function and improvement in LV suction, or it may occur because of raised filling pressures and transition of grade I to grade II disease. Documentation of changes in diastolic function is difficult to interpret in any patient, and no less in those with hypertensive heart disease. In a randomized study of angiotensin receptor blockade, no significant change in e' was witnessed between valsartan and the control group.\textsuperscript{175} Nonetheless, other studies have shown that improvements in LV geometry after treatment in hypertensive patients with ECG evidence of LV hypertrophy have been associated with parallel improvements in Doppler-derived indices of diastolic function.\textsuperscript{176}

**Recommendations**

While echocardiography has been key in demonstrating the beneficial effects of hypertension treatment in large cohort studies, routine reassessment of echocardiograms to examine treatment response in hypertensive subjects is not recommended, due to the limited reproducibility of measurements on an individual patient basis. Follow-up echocardiograms may be of value to assess changes in symptom status.

**ECHOCARDIOGRAPHY IN CLINICAL MANAGEMENT OF HYPERTENSION**

**Stratification of Risk in Hypertension**

The value of transthoracic echocardiography is recognized in the 2013 ESC/ESH guidelines,\textsuperscript{167} where it is listed as a class II indication (level of evidence B) for cardiovascular risk assessment in asymptomatic adults with hypertension.\textsuperscript{177} Transthoracic echocardiography received a high appropriate use criteria score of 8 (scale 1–9) for the initial evaluation of suspected hypertensive heart disease.\textsuperscript{178} In this document, LV hypertrophy, LV diastolic dysfunction, and LA enlargement are described as specific signs of hypertensive heart disease. LV hypertrophy is recognized as evidence of target organ damage in hypertension by the Joint National Committee for the prevention, detection, and evaluation of high blood pressure (JNC 7) of the National High Blood Pressure Education Program (National Heart Lung and Blood Institute).\textsuperscript{177}

In patients with hypertension, the type of LV remodelling (concentric remodelling, eccentric hypertrophy, and concentric hypertrophy) is predictive of the incidence of CV events. In particular, the presence of LVH on echocardiography identifies hypertensive heart disease with a higher sensitivity and specificity compared with electrocardiography. Several population cohort studies have shown that LVH is predictive of cardiovascular and all-cause mortality, independent of blood pressure, and across all racial groups that have been studied.
In the predominantly white population of the Framingham Study, for every 50 g/m² higher left ventricular mass index, there was a relative risk of death of 1.73 (95% CI 1.19–2.52), independent of blood pressure level. In African-Americans enrolled in the ARIC study, LVH was associated with an increased risk of cardiovascular events (HR of 1.88 in men and 1.92 in women). Similarly, for Native Americans enrolled in the Strong Heart Study, echocardiographic LVH also had additive discriminatory power over ECG LVH; the prevalence of LVH on echocardiography was 9.5% and was associated with a seven-fold increase in cardiovascular mortality and a four-fold increase in all-cause mortality. Hispanic Americans showed a similar association of LVH and CVD mortality. International studies have also confirmed a similar risk for CVD in hypertensive patients with LVH. Concentric LVH on echocardiography identifies a high risk phenotype with abnormal flow-mediated dilation and decreased myocardial flow reserve.

In symptomatic adults with hypertension, the echocardiogram provides additional assessments for systolic and diastolic dysfunction, as well as evaluation of wall motion abnormalities to detect underlying coronary artery disease. The use of echocardiography during treadmill or pharmacological testing is indicated in hypertensive patients with symptoms suggesting CHD and/or to estimate prognosis in patients with known concomitant coronary artery disease as well as those with known or suspected valvular heart disease. Patients with LVH, as well as related problems (abnormal resting ECG, left bundle-branch block, electronically paced rhythm, and digoxin therapy), also warrant pharmacological stress echocardiography.

Investigation of Chest Pain Symptoms

Chest pain in patients with hypertension may signify concurrent coronary artery disease or may simply reflect subendocardial ischaemia due to LV hypertrophy and increased afterload. The diagnosis of coronary artery disease has particular challenges in this setting, because ‘false-positive’ results may occur when subendocardial ischaemia causes abnormal stress ECG or myocardial perfusion scan in the absence of flow-limiting epicardial coronary disease. A normal stress electrocardiogram, performed to a high workload, has a high negative predictive value, but an abnormal or ambiguous test warrants further evaluation. There is some evidence in favour of preferential use of stress echocardiography for this purpose, because stress-induced wall motion abnormalities are highly specific for coronary artery disease, while perfusion defects in hypertensive patients may arise from abnormal myocardial flow reserve not due to epicardial coronary disease. The lack of specificity of the coronary flow signal for epicardial coronary artery disease is also a problem when stress echocardiography is combined with the assessment of coronary flow reserve in hypertensive patients. Finally, although hypertensive patients are at increased risk of coronary artery disease, screening for coronary disease is not recommended in asymptomatic patients because of the risk of false-positive results and uncertain management responses.

Role in Decision to Initiate Treatment

Effects of antihypertensive agents on LVM and other echocardiographic surrogate endpoints (e.g. LA size and diastolic function) have been extensively studied. Several large studies sponsored by the National Institutes of Health and the US Veterans Administration Cooperative Studies program have evaluated the effects of antihypertensive monotherapy. In general, it appears likely that there are differences between the efficacy of antihypertensive drugs and their effects on LVH. LVH regression does not adversely affect cardiac function and may be associated with improvements in diastolic function. However, although the finding of increased LVM on echocardiography could potentially guide selection of initial or intensity of therapy in hypertensive patients, JNC 7 recommendations do not risk stratify patients for treatment on the basis of target organ damage. Current guidelines recommend the use of combination treatment to get blood pressure to goal, thus blood pressure remains the primary target of therapy.

A part of the problem with getting a more central role for echocardiography to guide therapy is that despite the adverse prognosis associated with LVH in hypertension, there are inconsistent data from numerous studies that have evaluated the comparative efficacy of specific antihypertensive agents in LVH regression, as well as survival benefits associated with LVH regression. In a meta-analysis of 39 trials of antihypertensive therapy, angiotensin-converting enzyme inhibitors were the most effective agents, leading to a 13.3% reduction in LVH compared with 9.3% for calcium channel blockers, 6.8% for diuretics, and 5.5% for beta-blockers. However, in a comparison of enalapril and long-acting nifedipine in patients with essential hypertension, the PRESERVE (Prospective Randomized Enalapril Study Evaluating Regression of Ventricular Enlargement) trial, systolic and diastolic pressures, as well as LV mass were reduced to a similar degree with both agents. On the other hand, the LIFE (Losartan Intervention For Endpoint Reduction in Hypertension) trial echocardiographic substudy demonstrated superior LVM reduction (21.7 g/m²) in patients treated with the angiotensin receptor blocker losartan compared with those treated with the beta-blocker atenolol (17.7 g/m²). Finally, despite a 20% incidence of LVH regression with placebo, diuretic therapy with chlorothiazide and hydrochlorothiazide, respectively, demonstrated greater LVH regression over alternative agents in both the TOMHS (Treatment of Mild Hypertension Study) and Department of Veterans Affairs Cooperative Study Group on Antihypertensive Agents. Similarly, left atrial size itself a predictor of adverse outcomes was reduced with hydrochlorothiazide.

In the recently defined category of pre-hypertension (systolic blood pressure 130–140 mmHg and/or diastolic blood pressure 80–90 mmHg), JNC 7 recommends intense lifestyle modification in such patients. Clinicians may obtain echocardiography to evaluate the presence of LV hypertrophy in such patients with prehypertension, particularly where there is a strong family history of hypertension and cardiovascular complications including stroke, heart failure, or dialysis. The community practice consensus is that the presence of LVH in such patients should lead to more aggressive approaches to lifestyle modification. There is increasing recognition that data on target organ involvement, including echocardiographic LVH, may be important for young adults whose lifetime risk for hypertension is currently underestimated by most risk stratification models. However, no studies have examined whether a patient’s knowledge of echocardiography demonstrating LVH will improve adherence to lifestyle modifications or pharmacological treatment of hypertension.

According to the National Health Service and National Institute for Health and Clinical Excellence (NICE) recent guideline update on the clinical management of primary hypertension in adults, there is uncertainty about how to assess the impact of blood pressure treatment in people aged <40 years with grade 1 hypertension and no overt target organ damage or CVD. In particular, it is...
not known whether those with untreated hypertension are more likely to develop target organ damage and, if so, whether such damage is reversible. The writers of the NICE guideline further observe that target organ damage as surrogate or intermediate disease marker for CVD or hypertensive heart disease is the only indicator that is likely to be feasible in younger people because traditional clinical outcomes are unlikely to occur in sufficient numbers over the timeline of a typical clinical trial.

Role in Decisions to Intensify Treatment
The decision to intensify treatment of hypertension is currently guided by monitoring of clinic as well as home blood pressures. In patients who have hypertensive heart disease with L VH and normal systolic function, the value of periodic echocardiographic follow-up is not established; the Appropriate Use Task Force gave a score of 4 (may be appropriate) based on insufficient data for a stronger recommendation, regarding the re-evaluation of known hypertensive heart disease without a change in clinical status or cardiac examination.178 However, echocardiography may be helpful in several scenarios. Patients with hypertensive heart disease who become symptomatic require follow-up echocardiography to evaluate systolic and diastolic function. Dissociation between blood pressure measurements and LV hypertrophy is an indication for further testing. The detection of high blood pressure without hypertrophy should lead to consideration of overestimation of the severity of hypertension, including ambulatory blood pressure monitoring or measurement of central aortic pressure.195 When there is apparent LV hypertrophy in the setting of apparent blood pressure control, more detailed blood pressure evaluation (e.g. for masked hypertension) or identifying other causes of wall thickening such as infiltrative diseases should be considered.

Use of Echocardiography to Monitor Response to Antihypertensive Treatment
There is no current indication for the use of echocardiography to routinely monitor antihypertensive therapy, except as indicated and described in the section above for symptomatic patients or for patients with poor control of blood pressure. A recent intersocietal consensus document178 on the appropriate use of echocardiography in clinical practice characterized its routine use for patients with hypertension without symptoms or signs of heart disease as ‘rarely appropriate’ with a value score of 3 out of 10.

Relevance of Hypertension to Echocardiographic Interpretation
Afterload is an important determinant of the assessment of cardiac function from ejection phase indices. Consequently, hypertension may have an important effect on the assessment of LV function in a variety of conditions. For example, an increment of blood pressure between visits may lead to an apparent deterioration of LV function when serial echocardiograms are being performed during chemotherapy or in the evaluation of valvular heart disease. In the assessment of aortic stenosis, arterial hypertension and the stenotic valve behave like serial resistors, and their combined impedance may explain symptom status.196 Likewise, in stress echocardiography, hypertension—especially a hypertensive response to stress—may provoke wall motion abnormalities or global LV dysfunction in the absence of coronary disease.197 However, the impact of hypertensive LVH is probably less than in perfusion scintigraphy, where abnormal coronary flow reserve may produce false-positive perfusion abnormalities in the context of normal wall motion.198

Recommendations
At present, decisions regarding the initiation, intensification, or monitoring of response to antihypertensive therapies are made based on clinical parameters. Given the progressive nature of hypertensive cardiomyopathy, periodic evaluation of cardiac function and morphology by echocardiography may be warranted, especially if symptoms change.

RECOMMENDATIONS FOR CLINICAL LABORATORIES
The value of echocardiography as a research tool in hypertension is uncontented. In a relatively short time, it has defined the cardiac structural and functional effects of hypertension, determined the prevalence of LVH and LV remodelling, determined the cardiac effects of antihypertensive therapy, and in epidemiological studies, provided fundamental insights into the relationships between blood pressure, genetic susceptibility, and LV mass. However, although it has been suggested that treatment choices in individual patients should be guided by echocardiographic findings, the value of echocardiography in the clinical management of hypertension is unproven.

The benefits of echocardiography will depend on its value in affecting treatment decisions, and in early identification and intervention in patients at risk who would not otherwise be treated. Moreover, demonstration of a value requires that the impact of echocardiography on clinical decisions is accompanied by improvement in patient outcome. Importantly, any consideration of the utility of echocardiography is contingent upon its reliability for the assessment of target measures such as LVM. However, little information is available on the impact of echocardiographic data on physician behaviour, or on patient outcomes in hypertension.

Previously, World Health Organization-International Society of Hypertension (WHO-ISH) suggested that drug treatment could be withheld in hypertensive individuals with low cardiovascular risk based on non-echocardiographic criteria. However, echocardiographic findings in such individuals increase risk classification in 29% of such cases,196 suggesting a role for echocardiography in risk profiling. However, recommendations for drug therapy at lower blood pressure levels may have made this application of echocardiography moot.

Another important limitation on the wider use of echocardiography is cost, both relative to benefit, and in competition for economic resources. In the USA alone, approximately 76.4 million adults have hypertension.199 At even the arguably modest current Medicare/Medicaid reimbursement for echo of $238, one echo per patient with hypertension would cost $181.2 billion. Justification for this expenditure as an additional billable item would be difficult to provide. However, the development of hand-held ultrasound would allow suitably trained practitioners to obtain LV wall thickness and dimension information as part of the office visit. The effectiveness of this strategy remains unproven, especially in the light of training requirements, concern about interobserver variability, lack of standard quality assurance standards, and the increase in time for an office visit.

Given the above considerations, it has been recommended that echocardiography be reserved for those individuals with hypertension in whom hypertensive cardiac disease or cardiac disease in association with hypertension comorbidities is suspected. In such cases, a complete 2D and Doppler study should be performed, and the study...
not limited to evaluation of LVM/LVH. While calculation of LVM can readily be performed utilizing standard methods, variability can be quite large, and current evidence does not support using LVM measurement to either initiate or modify hypertension treatment.

**RECOMMENDATIONS FOR RESEARCH STUDIES AND CLINICAL TRIALS**

Table 8 lists some potential areas where echocardiography (or other imaging) may help to guide management decisions in hypertension. The role of imaging in these settings is unproven and warrants further study.

Acquisition and interpretation of echocardiograms for research purposes in hypertension poses some special challenges. Even for clinically experienced sonographers, there is a significant learning curve present in recording technically adequate echocardiographic studies for the assessment of LVM, particularly in older subjects. In a Framingham analysis of M-mode echocardiograms performed in over 6000 subjects aged 17–90, the ability to record acceptable quality echocardiograms in subjects older than 60 years rose from a minimum of 28% during the first 5 months of the study to a maximum of 74–81% during studies 2 years later. Hence, echocardiography ‘drop-outs’ may not be randomly distributed, leading to the possibility of bias in data interpretation. Two-dimensional echocardiographic measurements were even more problematic than 2D-guided M-mode.

In previous large echocardiography trials, major differences in echo quality have existed between field centres. For example, in a 15 centre ventriculo-arterial trial of antihypertensive monotherapy, the percent of readable echocardiograms for LVM varied from ~30 to 85%. This was not due to differences between centres in the proportion of easy or difficult patients. While the use of suboptimal equipment in some cases contributed to poor studies, the intercentre differences were mostly because of variation in technical performance. Importantly, extensive previous clinical experience in echocardiography was no guarantee of high-quality echocardiograms for research purposes.

There is potential for differences in image acquisition styles that may exist between field centres in epidemiology studies, potential effects of instrumentation, continuing improvement in quality images obtained with newer generations of echo machines, and temporal intrareader drift in echo measurements and interpretations (e.g. LV walls may be read as thicker, or thinner at the beginning than the end of the clinical trial or observational study). All of these may produce not just large random variability in measurements and qualitative assessments, but substantial biases. For example, a temporal drift where readers might tend to read smaller wall thicknesses after months to years of experience with the study and patients receiving several treatments in the absence of a placebo control (common if not ubiquitous in clinical hypertension trials) may lead to the mistaken conclusion that both treatments are associated with decreased LVM and decreases in the proportion of individuals with LVH.

Several principles learned from clinical trials are applicable for echocardiography. The acquisition of reproducible, correctly oriented images requires sonographer training. Monitoring of study quality is important. The inclusion of ‘control’ subjects is a protection against apparent changes due only to regression to the mean. The use of sample echocardiograms is a means of ensuring that all team members are applying the same methodology, and to prevent ‘drift’ over time.

**Recommendations for Echocardiography in Hypertension Clinical Trials**

Given the large confidence intervals that may exist for measurement of LVM, it could be argued that treatment trials should recruit participants with markedly increased LVM. However, selection of participants with values for LVM values substantially above (or below) the population mean can result in subsequent tests that reflect regression to the mean. Therefore, higher than ‘true’ values for LVM on an initial determination will tend to decrease on subsequent measurement. It is recommended that if possible, partition values for LVM not be used as requirements for entry into the study. If such values are used, then batch reading at completion of the study (with continuous monitoring of studies for acquisition quality) should be done. This may not be practical in long-term studies.

In creating categorical variables (e.g. LVH, LA enlargement, and abnormal annular tissue velocity), it is advisable when possible to use comparative control subjects from the same study to generate partition reference values. This is often possible in observational or epidemiologic studies, where participants without clinically prevalent disease (or better still—free of subclinical disease as well) can be utilized to derive partition values for continuous variables. Where those values are affected by age, body weight, height, gender, etc.—reference values can be derived from regression models used to derive a predicted value (with confidence limits) and express abnormality of a parameter by determining its ratio to this predicted value. However, this may not be possible in many clinical trials.

In large multicentre observational studies and clinical trials where all studies are read by a single core laboratory, the volume of studies can quickly become overwhelming. Special considerations exist re: management of workflow, but also vetting of site sonographers, participation in trial design, statistical power estimations, provision of ongoing quality assurance and improvement, data transmission to the statistical core, and issues regarding participant and investigator clinical alerts for abnormal findings. Specific considerations regarding core laboratory best practices have been described in a previous ASE EACVI expert consensus statement.
